Chapter 5

HALUCINATIONS

Perception is the process of converting physical stimulation, such as light waves arriving at the eye, or airwaves arriving at the ear, into psychological information.

Hallucinations are false perceptions – that is, perceptions in the absence of external stimuli – i.e., hearing voices or seeing people when no one else is present.

Hallucinations may result in secondary delusions – they may lead in to inaccurate “explanations” of what is happening.

Hallucinations in healthy people

Hallucinations may be experienced in the absence of mental or other medical disorders. Such experiences have been recorded for hundreds of years.

Not to offend anyone – but the religious traditions describe similar phenomena.

The ‘hearing’ and/or ‘seeing’ a deceased family member occurs in about 56.6% of bereaved people (Kamp & Due, 2019).

Hallucinations may occur in those lost in the wilderness.

Sigmund Freud, the father of psychoanalysis wrote, “During the days when I was living alone in a foreign city. I quite often heard my name suddenly called by an unmistakable and beloved voice...”

Mahatma Gandhi relied on an “inner voice” for guidance. Toward the end of his life the voice said, “You are on the right track, move neither to your left, nor right, but keep to the straight and narrow.” Other people of great resolve have also described similar “inner voices”.

About 13.2% of healthy adults may “hear voices” (Beavan et al, 2011).

A recent study of healthy 12-19-year olds, in Ireland, found auditory hallucinations in 13.7%, and visual hallucinations in 13.1% (Dolphin et al, 2015).
Hallucinations, usually a voice calling the individual’s name, are sometimes heard by healthy people as they pass from waking to sleeping (hypnogogic hallucinations). This also occurs with passing from sleeping to waking (hypnopompic hallucinations).

There are usually differences between the voices heard by healthy individuals and the hallucinations of those with mental disorders. In healthy individuals, the voice is usually as if from one person, speaking comprehensibly, in a helpful and comforting manner. Auditory hallucinations in mental disorders, in contrast, may involve more than one voice, sometimes arguing, sometimes stating that the individual is ugly (Waite et al, 2019), frequently making little sense, and often in a threatening or frightening manner.

**Hallucinations – in organic brain disorders**

**Epilepsy** may feature hallucinations. Frederic Chopin experienced hallucinatory episodes throughout his life – possibly the result of epilepsy (Vazquez & Branas, 2011).

**Charles Bonnet syndrome** is the experience of nonthreatening visual hallucinations experienced by patients who are free of neurological and psychiatric disorder, but who have significant visual impairment secondary to ocular disease (Jackson & Madge, 2011).

Hallucinations occur in **Neurocognitive disorders**. Among people with Parkinson’s disease and psychosis, 92.5% experienced hallucinations – most commonly visual, and there are rare cases of olfactory hallucinations (Amar et al, 2014). In Parkinson’s, Alzheimer’s disease, and Dementia with Lewy bodies, the frequency of visual hallucinations is significantly associated with the density of Lewy bodies. In Parkinson’s the frequency of visual hallucinations is also significantly associated with the density of plaques and tangles (Jacobson et al, 2014).

Hallucinations may occur with many **other brain disorders** including tumour, multiple sclerosis, and the very recently described Autoimmune Encephalitis (see Chap 36) (Grewal et al, 2018). In these conditions, visual hallucinations are the most common.

**Hallucinations – in drug (legal and illegal) use**

Hallucinations occur with some medically prescribed medications, for example, the anaesthetic drug ketamine, and some drugs used in the treatment of Parkinson’s disease. Illegal drug use is commonly motivated by the desire to experience hallucinations and illusions (visual, auditory, somatic, tactile) - but frequently, there is an unplanned descent into psychosis.

Three models of hallucination/psychosis generation (Dopamine, Glutamate and Serotonin) have been proposed (Rolland et al, 2014).
## Hallucinations – three models

<table>
<thead>

Hallucinations – three potential neurobiological mechanisms (Rolland et al, 2014).

### Hallucinations in mental disorders

**Auditory** hallucinations (in mental disorders) are usually of voices. However, “non-verbal” auditory hallucinations occur - these include clicking and mechanical noises, muttering or mumbling, and music. (In musical hallucinations the patient often hears a complete piece of music.) Auditory hallucinations are most common in psychotic disorders such as schizophrenia, but they also occur in the mood disorders, and occasionally in borderline personality disorder (Beatson et al, 2019).

In the case of verbal auditory hallucinations (voices), these may be heard inside or outside the head. Voices outside the head can be identified with confidence as hallucinations – voices inside the head may require some caution as they be difficult to distinguish from thinking.

One or more different voice may be heard. In the case of more than one, these can be heard sequentially or simultaneously. Two or more voices may conduct a conversation between themselves. A voice or voices may speak to the patient or about the patient. They may comment on his/her thoughts or actions. Voices are usually heard as speaking, but they may be heard singing or shouting. Voices rarely speak in complete sentences - they usually say a few disjointed words in brief utterances. While the content of auditory hallucinations may be clearly understood by the patient, frequently it is not.

The patient may recognize the voice because it has been heard before, either firsthand or via the media. Voices usually do not introduce themselves, e.g., “This is God speaking” - is almost never heard. It may be that the patient has never heard the voice before, but nevertheless “knows” who is speaking. It is often God, Jesus, Satan, a member of a covert spy agency, criminals or the leader of a bikie gang. Voices can be from relatively benign sources such as a former next-door neighbour, but they are almost never from kindly disposed individuals such as a favourite early schoolteacher, Mary Poppins or Peter the Rabbit.
Uninvited, disturbing voices may be resented. On the other hand, somewhat surprisingly, voices (even insulting ones) may become “company” for the isolated individual - in which case they may become welcome.

This note was pushed under the office door of the author, by a known patient. The patient began to hallucinate the author’s voice at night. While there had been a good patient-doctor relationship, the last line “Leave me alone!” suggests irritation.

**Command hallucinations** - voices may instruct or command the patient to perform an act. Usually this is a trivial act such as making a cup of tea, but it may be to injure him/herself or others. Importantly, patients do not automatically comply with command hallucinations. When a command is first given, the words are usually spoken, perhaps with a hint of insistence. For some patients, when command hallucinations are ignored, there are no consequences, the command is not repeated, or may be repeated essentially in the same relatively benign manner. In these conditions the patient is usually able to continue with his or her activities.

In other cases, however, when commands are ignored, they are repeated with much insistence, perhaps shouted with abuse. Generally, patients do not like complying with command hallucinations, perhaps because to do so threatens their sense of autonomy. However, it is very distressing to be subjected to repeated, raised, abusive voices. A common response of patients is to comply with the trivial commands such as, “Look out of the window”, and to resist the uncomfortable or dangerous ones such as, “Jump out of the window”. Command hallucinations are **not** a common factor in homicide.
In fifty years in clinical practice, the author has known only two or three cases in which a person has complied with hallucinations telling him/her to seriously injure him/herself. This is one; a man with schizophrenia was instructed to chop his arm off.

Verbal hallucinations may be a feature of elevated or depressed mood, in which case the adjective ‘psychotic’ is attached to mania or depression. In the case of elevated mood the hallucination may assert the patient has exceptional beauty, intelligence or other qualities: “We know you’re the king”. In the case of depressed mood, the hallucinations may denigrate, “You rat. You should die”. They may suggest or command suicide. The patient may comply, but usually resists.

About 42.6% of those with bipolar disorder experienced hallucinations (73.8% experienced delusions) (Van Bergen et al, 2018). The rate is higher with more severe disorder.

Recent reports have stated that PTSD commonly features verbal (and to a lesser extent visual) hallucinations. This is a current matter of debate - Clifford et al (2018) found no support for auditory hallucinations in PTSD, but Cheng et al (2019) reported beneficial effects of antipsychotics.

Visual hallucinations occur in a range of disorders. They occur more frequently than auditory hallucinations in people with neurological disorders. In some types of epilepsy visual hallucinations may form complex scenes such as two trucks and a rickshaw driving through the room. In migraine, a common disorder of people who do not have a mental disorder, visual hallucinations may have the form of circles or lines in space across the visual field.
In schizophrenia, visual hallucinations occur in about 27% of patients (Cachia et al., 2015) - they are often indistinct or distinct figures, usually humanoid, standing to one side of the room. They frequently pass unreported to clinical staff – they are not (usually) distressing, and the patient has many more pressing concerns.

This note was written by a man with schizophrenia. It tells of seeing a visual hallucination of “a missile as plain as I see you”. In schizophrenia, detailed visual hallucinations such as this are much less common than auditory hallucinations.

Tactile hallucinations are the experience of being touched or of a crawling sensation under the skin. These are common in drug withdrawal states but may occur in schizophrenia.

Somatic hallucinations are the sensation of things happening inside the body, such as organs moving from one region of the body to another. These are rare but may occur in schizophrenia.

Gustatory/Olfactory hallucinations - the hallucinations of taste and smell, are more common in neurological disorders, particularly epilepsy, but may occur in schizophrenia. A study by Langdon et al (2011) found olfactory hallucinations in 15% of patients with schizophrenia, and some patients with social anxiety and depression. The authors suggested that people are more reluctant to talk about smells than voices, and this type of hallucination may be more common than is generally recognized.
Autoscopic (self see) hallucinations are the visual experience of the subject/patient seeing an image of him/herself (or parts of). This is a rare symptom which takes many forms and is mentioned only as a curiosity – no student will fail an exam through lack of familiarity with autoscopic hallucinations.

Brugger et al (1997) developed a classification - 6 types: 1) only parts of a ‘double’ are seen (e.g., face, torso), 2) the ‘double’ is complete (this is the “doppelganger” which appears in folklore and literature), 3) the feeling of a presence (no double is actually “seen”), 4) out-of-body experience (the individual is outside and looks back at their own body), 5) negative autoscoppy (the individual is unable to see their own body either when looked at directly, or in a mirror), and 6) inner (internal) autoscoppy (the inner organs are seen outside the body).

Autoscopic hallucinations occur more frequently in neurological disorders (seizure disorder, alcohol withdrawal) (Dening & Berrios, 1994), but can occur in psychotic disorders and stressful situations.

Some other perceptual difficulties include heightened and changed perceptions - in heightened perceptions, sounds seem unnaturally clear, loud or intense, colours appear more brilliant or beautiful, or details of the environment seem to stand out in a particularly interesting way. Changed perceptions - changes are perceived in the shape or size of people and inanimate objects in the environment. Changes may continue while the patient watches. Psychotic patients may be difficult to engage in conversation because they are distracted by continuously changing perceptions. Patients may spend long periods looking in a mirror, watching their own face change.

Heightened and changed perceptions occur in psychotic disorders, but have also been reported in non-psychotic, anxiety disorders.

Illusions are perceptions that are associated with an outside stimulus (thus, they are not hallucinations) - but the stimulus is wrongly interpreted. For example, lapping water may be heard as laughter. Illusions are frequently visual, and they are usually the result of a neurological disorder. The condition which most commonly causes illusions is delirium tremens (DTs), the disturbed state which can complicate alcohol withdrawal. Objects such as creases in bed covers may be perceived as snakes, insects or other small animals.
Summary: Circumstances and disorders associated with hallucinations.

“Normal Hallucinations”
- Religious experiences, often in group settings
- Sleep deprivation, voluntary or forced
- Isolation
- Sensory deprivation (Charles Bonnet Syndrome)
- Bereavement
- Hypnogogic and hypnopompic

Drug Induced
- Illegal drugs, LSD, volatile substances
- Legal drugs, Ketamine, Parkinson’s disease treatments

Drug Withdrawal
- Alcohol – these are generally illusions rather than hallucinations

Neurological Disorders
- Temporal lobe epilepsy
- Parkinson’s and Alzheimer’s diseases
- Dementia with Lewy bodies
- Uncommon: multiple sclerosis, brain tumour, autoimmune encephalopathy

Mental Disorders
- Schizophrenia, usually voices, but other types also
- Mood elevation (mania) not common
- Mood depression, in severe forms only.
- PTSD – in debate

Table. Circumstances and disorders in which hallucinations may be experienced.

Neuroimaging

Functional imaging studies of auditory hallucinations in schizophrenia (Geoffroy et al, 2014) confirmed disruptions of the white matter integrity in the left arcuate fasciculus.

The arcuate fasciculus, bi-directionally connecting Broca’s (left inferior frontal gyrus; IFG) and Wernicke’s (left superior temporal gyrus; STG) speech centres.
Kose et al (2018) reviewed reports of cortical thickness in patients with auditory verbal hallucinations – and reported reduction in the **transverse temporal gyrus** (also known as **Heschl’s gyrus** and the **primary auditory cortex** – it is buried in the lateral sulcus), the **STG** and the **middle temporal gyrus**.

Zhang et al (2018) used diffusion tensor imaging to study schizophrenia with auditory verbal hallucinations – they found white matter abnormalities in tracts connecting the speech generation, speech perception and verbal memory networks.

Lin et al (2019) reported increased global functional connectivity (GFC) density in the bilateral superior temporal gyrus and mesial frontal lobe and decreased GFC in the bilateral medial prefrontal cortex.

Kim et al (2019) studied 89 brain lesions causing hallucinations using “lesion network mapping”. They found these all fell within a single functionally connected network defined by connectivity to the cerebellar vermis, inferior cerebellum, and the right superior temporal sulcus – lesions causing visual hallucinations were connected to the lateral geniculate nucleus in the thalamus – lesions causing auditory hallucinations were connected to the dentate nucleus in the cerebellum.

**E/I imbalance theory of hallucinations**

Jardri et al (2016) propose hallucinations are the result of abnormalities in the ratio of excitatory to inhibitory cortical activity.

**Neurofeedback for hallucinations**

Neurofeedback has a place in helping people learn to relax – electrodes are placed on tight muscles - electrical activity is detected and a speaker emits a variable note. When the muscles relax the note changes. So, patients are asked to try to change the auditory signal – in doing so, they improve relaxation skills.

Auditory hallucinations (voices) arise [according to some] due to increased activity in the speech region of the left superior temporal gyrus. Using real-time fMRI patients were able to down-regulate the activity in that region and increased functional connectivity between the left superior temporal gyrus and other speech related areas was modified (Orlov et al, 2018; Zweerings et al, 2019). At this point there is no suggestion this procedure has clinical application.

**Cognitive Behaviour Therapy (CBT) for Psychosis**

Cognitive behaviour therapy (CBT) for psychosis is a relatively new treatment and is not widely available. It is applied in addition to usual care.
Ontario (2018) and Paulik et al (2019) claim encouraging results, in the management of hallucinations, but substantial benefits are yet to be demonstrated.

APPENDIX

CASE HISTORIES

Case history: 1

Cynthia Campbell was 17 years of age and attended a local Catholic school. She lived with her parents and 15 year old sister, Melissa, in a middle class suburb of a large city. Her only other sibling, Libby, was older, in the Army, and stationed overseas. Cynthia’s mother was a dentist and her father was a fireman.

Cynthia had been distressed. She was about to leave high school but didn’t have a clear plan for the future. She had found schoolwork difficult, and although she had daydreamed about becoming a teacher and helping children like herself, who had struggled, she was adamant that she would not go to university. She liked the idea of a job in a plant nursery. That would mean a part-time Technical College course, but she thought she could probably manage. She knew some sort of qualification was essential for a comfortable working life. The problem was that jobs were few and far between. If all else failed, she could join the Army, like Libby. Although, her father had said he didn’t want her to go in that direction.

She had just broken up with Sam, an 18 year old who was attending a different school. She had loved him, he was her first intimate lover, but he had found someone else.

When she was going out with Sam she started smoking some marihuana at parties on Saturday nights. On one occasion she took one “speed” (amphetamine/stimulant) tablet. Since the break-up she had sought a supplier of marihuana and had smoked after school two or three times a week.

A week ago, when she was smoking at her girl-friends house she heard her father’s voice. She quickly stubbed her “joint” out, grabbed Emily’s joint and stubbed that out, pushed the ashtray under the bed, and pretended to be reading a magazine. Emily looked at her quizzically, “What’s up your knickers?” she asked.

“Shhh. My father’s out there,” Cynthia replied, flapping her magazine to disperse the residual smoke. For a moment, Emily was startled, “How do you know?” she whispered.

It soon became clear that Mr. Campbell was not in or near the house. “I just thought I heard his voice,” said Cynthia, making an effort to sound nonchalant.
A week later, while the family was having dinner, “That’s Libby…. She must be home!” Cynthia interrupted, dropping her cutlery and standing up from the table. She turned as if to run out of the room, but froze, standing, listening. “I didn’t hear anything,” said her father. “No. It couldn’t be,” said her mother. “She didn’t say she was coming.” “Yes. Yes it is,” said Cynthia. She continued to listen. Then they all went quiet and listened. Only Cynthia heard something.

There was a common sense of alarm. There was something wrong. Melissa was frightened and cowered down into her chair. Her parents stood up, not quickly, as when faced by an attacker, but questioningly. Cynthia’s expression changed from surprise and pleasure to bewilderment, through some level of comprehension to terror. “What’s happening! What’s happening!” she wailed, and began crying. Her parents took her from the table to the sofa and sat on either side.

Cynthia’s experience was of a voice from outside her head, which she heard. She could not say if it was a male or a female voice, but she heard her name clearly called. There were some other words and short sentences, most of which were muffled. What she heard did not seem to make much sense. As when she had heard her father’s voice at Emily’s house, the experience was totally convincing, but once it stopped Cynthia could agree, she had been mistaken. That is, she lacked insight while she was hallucinating, but she gained insight into her situation when the hallucination stopped and she was able to check with her companions.

Learning that this was the second of these events, and distressed by her distress, Cynthia’s parents insisted that she stay at home and rest the next day, which was Saturday. That morning she saw a palomino horse walk through the kitchen wall, turn left and walk down the hall before disappearing. She was calm and interested in the sight while this was happening, but terrified when it was over. She sensed that she had lost control over her mind and her environment.

Cynthia’s palomino horse experience startled her parents. They immediately arranged for her to see a general practitioner. They thought the roots of the problem may have been the break-up of her relationship with Sam and the pressure she was under to make decisions about what she wanted to do in life. Secretly, her father thought she could be pregnant. The general practitioner thought schizophrenia was the most likely diagnosis. A possibility which avoided them all was drug induced hallucinations.

A series of investigations were performed, including an electroencephalogram (EEG; attaching electrodes to the head to measure the electrical activity of the brain). The EEG revealed Cynthia was suffering a form of epilepsy. She was treated with medication for epilepsy and advised to avoid illegal drug. The hallucinations ceased. Epilepsy is associated with a physical brain abnormality, but can be worsened by emotional stress and the use of certain drugs, particularly mind-altering substances.
Case history: 2

Michael Wells was a twice married chef of 29 years of age. He lived with Holly, his second wife and her child from another relationship, in an inner Sydney tenement house. He had a son, Ned, from his first marriage; he rarely saw the boy as his ex-wife had moved interstate. Michael had a good job at a chef in a restaurant near his home.

“You’re not getting sick again, are you?” asked Bob, without smiling, as he pinned another order on the board.
“Absolutely not! Why? What’s the problem?”

Five years ago Michael had suffered an attack of schizophrenia. He had the delusion that Ned was going to be sold by his ex-wife, and hallucinations of voices and sirens. The most disabling symptom, however, had been his inability to think clearly. His thoughts kept slipping off track. He could not orchestrate his cooking, he could not get everything coming together and ready to serve at the same time. He would start thinking about one dish and then be distracted by another, and then another, and in the end, they would all be spoiled. Bob had very kindly kept Michael’s job open for three months, till he had recovered and was able to return to work. But now there was a note of apprehension and irritation in his voice, which suggested he would be reluctant to do the same again.

“You’re slow today. We’ll talk about it later,” Bob said over his shoulder, as he went back out to smile and greet and reassure people that their meals were well in hand.

Michael shook his head as if to clear it of sleep, and the look of concentration on his face increased. He pushed on, “Fuck off, fuck off, fuck off, fuck off…” he muttered, like a muted machine gun, to himself, from time to time. But not when Bob was in the kitchen. Michael’s output increased and the promised discussion did not eventuate.

He got an earlier appointment with his psychiatrist.
“I need to go back to the higher dose,” he said.

One month earlier, Michael had wanted to stop his medication. He discussed this with his psychiatrist. He made the point that he had been well for five years and that his medication had side effects: it reduced his sexual drive and made him tired. His doctor said that he was still at risk of a recurrence of acute schizophrenia, that things were going well for him, and that his relationship and his job could be at risk if he got sick again. In the end they decided it would be reasonable, in the first instance, to reduce his medication by half, and to reassess the situation in a month or so.

Michael found that he had felt much better on the reduced dose. He had more energy and he felt as if he was making progress. There had been no delusions and his thinking was still clear. The auditory hallucinations, however, had returned. He had two voices, both male. Sometimes they seemed to be outside his head, sometimes they seemed to be inside. It was similar to when he was sick, and he had known they were hallucinations from the day they came back, a week ago. Although he knew they were illness symptoms
and not “real”, it was hard not to listen to them, and they distracted him from what he was doing. They often commented on what he was doing and told him what to do. They sometimes got loud, insistent and abusive if he failed to comply.

“He’s separating the egg white,” one voice might say, when he was separating egg white for a sweet. Michael would find himself listening, to see if they were going to say what he should do next. It was comforting, in a way, they were company, even flattering. But then, “Add a teaspoon of water,” they might say. If a teaspoon of water was not a good idea, and he failed to comply, the voices, which usually spoke separately, might speak in unison. “Hey! Add a teaspoon of water!”

If he still failed to comply, the voices might shout (sometimes Michael was concerned that folks sitting in the restaurant would hear) and add insulting words. “ADD SOME WATER, YOU FUCKING PRICK!”

On occasions, even though he knew they were hallucinations, he would comply, just to shut them up. He resisted if their commands would ruin the meal, and thereby, his reputation.

The Psychiatrist explained that staying on the half dose of medicine had prevented a full relapse with loss of insight, but that there was now an immediate risk of a full relapse, which would probably mean further hospitalization. This warning was unnecessary. Michael’s recognized that his reduced productivity was threatening his job and returned to the higher dose of medication. The hallucinations quieted, then disappeared. He never had that talk with Bob. A year later he took Holly and his stepdaughter over the border to visit Ned.

Case history: 3

Pho Robertson was a 51 year old Australian citizen who was born in Vietnam. Her husband, Bill, died of an unexpected heart attack, two months previously. She lived in a comfortable four-bedroom home in a middle class suburb of Sydney. They had two children, both now married: Janice was in the Australian Embassy in Washington and Ken was unemployed and lived to surf.

Pho, the daughter of a schoolteacher and his wife, was raised in Saigon (Ho Chi Minh City). She had a good education, learning English and French and become a teacher in her late teens. For reasons which were never clear, her parents were imprisoned and she was exiled to a rural district. She did not see her father again; he died or was killed within a year of being imprisoned. She did not see her mother for another fifteen years.

Bill completed training as a surveyor. He found the last years boring and the thought of going directly into practice did not appeal. He joined the Army for some excitement. He was given a commission and was among the first Australian soldiers sent to Vietnam in
1967. He spent much of his time in the field, exposed to the danger of land mines and enemy fire.

Bill met Pho in a small village close to Nui Dat, the Australian task force base. She was beautiful; he was afraid. She was sad and fatalistic, but a comfort to him. In spite of his neediness, he was protective toward her. They talked of marriage, but there would be huge hurdles. Bill finished his tour of duty and came home. Although psychologically afflicted by his war experience, he volunteered for a second tour so that they could be together, at least for small amounts of time.

When he finished his second tour he came home, and Pho followed six months later. They settled in Bill’s hometown, Brisbane. There were many problems. Bill’s parents and siblings were not supportive. Many Australians thought Pho was Chinese or Japanese; when they learned she was Vietnamese, they behaved as if she was a communist and an enemy.

Bill and Pho were delighted when the children came along, and they could form their own complete, if somewhat socially isolated family. When the children were entering secondary school, Pho’s letter writing paid off and she regained contact with her mother. Bill had built up his own surveying company, they were doing well financially, and Pho was able to get the next plane to Vietnam to visit her mother. The old lady would not leave her native land, so over the years the family went to visit her three times.

Both the children were clever at school. Both had straight black hair and looked part Asian, but neither spoke of suffering significant racial prejudice. The girl was ambitious and proud of her heritage. She went to university with the intention of joining the diplomatic service. Her life had run according to plan. The boy was less ambitious. He started taking drugs in high school and did not seek further education. He married a waitress. It was an open secret that the couple made a fair living growing marihuana, drifting from one coastal town to the next, staying one step ahead of the law.

Bill suffered posttraumatic stress disorder following the war. He felt like a weakling because Pho’s experiences seemed worse than his, but she had not been damaged. Along with most other Australian Vietnam War Veterans, Bill felt betrayed by his country. They had been sent to fight and risk their lives overseas, but on return, they were criticized rather than appreciated for carrying out their orders. Then, along with others, either out of guilt or wisdom, Bill got involved in rebuilding Vietnam. Gangs would go, taking tools and materials, and build a school or orphanage or anything else they could put up in about a month.

He was buying roofing materials for a dormitory when, at fifty-five, he fell down dead in a Sydney parking lot.

Pho cried little. The children had come home for a week and she had looked after them. She was sad, had lost her appetite and had difficulty sleeping. She expected and accepted these difficulties. She did not expect to ever be happy again, or to eat or sleep well. She
was in a foreign country and had lost the husband who had been her best friend, her financial supporter and only lover. But, she had not expected hallucinations.

On the night of Bill’s death she did not sleep, she did not go to bed, she sat in the living room, she had his picture on the coffee table but she stared at the wall. About four in the morning she heard Bill say, “Don’t worry sweetheart…We can fix it.” For a cruel instant, she was bewildered. “He is alive, it’s a big mistake”, she thought. But then, she realised that Bill was indeed dead, and thought she must have heard his ghost. Then she concluded that it must have been a dream, and she must have drifted off to sleep for a moment, without noticing.

Next afternoon, she was sitting in the same chair, staring at the wall. She glanced over at Bill’s chair, and there he was in his dressing gown reading something. He raised his head and smiled back at her. He was calm and loving. He went back to his reading. She looked away, not knowing what to do, when she looked back, he was gone.

Pho heard and saw nothing of Bill in the week the children were at home. Or any other time when people were around. She only saw him twice more. One Saturday afternoon she went into their bedroom and he was having his afternoon nap on the bed. She froze. Not out of fright, but so as not to wake him. She looked at him, he was perfect in every way. There was grease on his cheek from the lawnmower. After a good long drink of looking at him she backed out of the room to let him sleep. It felt warm to have him there. When she went back half an hour later, sadly, he was gone.

The last time she saw him was a week later. She had been to the lawyer to finalize something she didn’t understand about the company. As she came slowly up the drive, he was standing on the lawn. Their eyes met and his look of concentration softened and he raised his eyebrows in recognition. She drove into the garage, when she came out, he was gone.

Pho didn’t believe in ghosts. Vietnamese culture is awash with various deities, but these experiences did not fit with anything she could accept. She knew little of mental disorder. In the first few weeks she did not care if she was mad or not. The day before going to the doctor, she heard Bill speak to her again.

The earth had settled on his grave. She had gone to the stone mason to talk about a headstone and was undecided about black or red granite. It was something which once done could not easily be undone. As she sat in the car, after the drive home she heard him say, “Black or red? It’s not worth worrying about.” She looked over to the passenger seat and the back seats, she would have liked to see him, but he wasn’t there.

“I’m going mad,” she told the doctor. “But, I like hearing his voice. I know I shouldn’t. Is there something you can do, to stop me getting worse?”
Pho was given reassurance by her doctor and seen twice a week to talk and keep working through the grieving process. The doctor later recommended Pho spend some time with a psychotherapist to look at the other losses of her life. At one point she took a small amount of sedation to help her sleep. Her hallucinations ceased without antipsychotic or antidepressant medication. Pho eventually visited her daughter in Washington, which she enjoyed greatly, and on return, she started corresponding with an American Vietnam veteran.

The hearing or seeing of a close, recently deceased friend or relative is not a mental disorder. Figures are not available, but this is a common experience. Usually these hallucinations become less frequent and cease over weeks or months. They are comforting and benign. Perhaps they have a role in helping the individual adjust to the loss. Pho was raised in social, political and military turmoil. Although she had been an adult when she lost her parents, the circumstances were still damaging. She was powerless, she did not have reliable information regarding their fate; thus her grieving for them was disrupted and protracted. She was traumatized by war. She migrated to a foreign land, peopled by another race, where she experienced prejudice. She was relatively isolated. Her main social network and support was her family. Her children left home and the vicinity. When her husband died she lost most of her human contact. While there is no clear evidence that persons with limited social supports experience more hallucinations during bereavement than those people with extensive social supports, such a finding would not be unexpected.

The grieving process is also normal and should not be confused with a depressive disorder (major depressive disorder of dysthymia). A depressive disorder may, however, develop following bereavement, and should be considered when the suffering persists for months or progressively worsens rather than improves.
